

1 The RSA Cryptosystem

1.1 Mechanism

Goal: Alice wants to send Bob an encrypted message through an insecure channel.

- Bob chooses his public key $(n, e) \in \mathbb{N}^2$ and private key $d \in \mathbb{N}$. Bob publishes his public key.
 - $n \in \mathbb{N}$ is called the modulus, with $n = pq$, where p and q are large distinct prime numbers. Note that Bob publishes n but keeps p and q secret.
 - $e \in \mathbb{N}$ is the called encryption exponent, and satisfies $\gcd(e, (p-1)(q-1)) = 1$.
 - $d \in \mathbb{N}$ is the called decryption exponent, and is determined by e and $n = pq$ via $d = e^{-1} \in \mathbb{Z}_{(p-1)(q-1)}$. Note that $e^{-1} \in \mathbb{Z}_{(p-1)(q-1)}$ exists since $\gcd(e, (p-1)(q-1)) = 1$.
- Alice
 - chooses plaintext $m \in \mathbb{Z}_n = \mathbb{Z}/n\mathbb{Z}$.
 - encrypts her plaintext m using Bob's public key (n, e) by **raising $m \in \mathbb{Z}_n$ to the e^{th} power**. In other words, Alice computes her ciphertext $c = m^e \in \mathbb{Z}_n$.
 - sends to Bob through the insecure channel the ciphertext $c \in \mathbb{Z}_n$.
- Bob decrypts the ciphertext $c \in \mathbb{Z}_n$ from Alice by **taking the e^{th} root** of c in \mathbb{Z}_n using his private key $d \in \mathbb{N}$ as follows:

$$c^d = (m^e)^d = m^{ed} = m^{1+k(p-1)(q-1)} = m \cdot (m^{(p-1)(q-1)})^k = m \cdot (1)^k = m \in \mathbb{Z}_n$$

- The second last equality follows from $m^{(p-1)(q-1)} \equiv 1 \pmod{n}$, which follows immediately from Euler's Theorem. It can also be justified with Fermat's Little Theorem as follows:

$$\text{Fermat's Little Theorem} \implies \begin{cases} m^{(p-1)(q-1)} = (m^{p-1})^{q-1} \equiv 1 \pmod{p}, \text{ and} \\ m^{(p-1)(q-1)} = (m^{q-1})^{p-1} \equiv 1 \pmod{q}. \end{cases}$$

Hence, $m^{(p-1)(q-1)} - 1$ is divisible by both p and q , and hence also by $pq = n$ (since p and q are distinct primes). Thus, $m^{(p-1)(q-1)} \equiv 1 \pmod{n = pq}$.

1.2 Comments

- One-way function (easy): Exponentiation in \mathbb{Z}_n .
 - Repeating Squaring Algorithm
- (Difficult) inverse function: Taking roots in \mathbb{Z}_n , for $n = pq$, where p and q are large distinct prime numbers.
- Trapdoor: If the factorization of $n = pq$ is known, then we can convert the inverse function (taking roots in \mathbb{Z}_n , which is slow) to an exponentiation in \mathbb{Z}_n , which is fast.

1.3 How to find large prime numbers?

- Generate a large N -bit (say $N = 1024$) random number x , i.e. $2^{N-1} < x < 2^N$. Use an efficient primality test to check whether x is prime. If so, we are done. If not, repeat until we succeed.
- The Prime Number Theorem (from Analytic Number Theory) gives an estimate of how many times we need to try before succeeding. The Prime Number Theorem states that

$$\lim_{x \rightarrow \infty} \frac{\pi(x)/x}{1/\ln(x)} = 1,$$

where $\pi(x)$ is the number of prime numbers less than or equal to x . Hence, it implies that, for large values of N , the probability that a randomly selected integer $x \in (2^{N-1}, 2^N)$ is prime is approximately

$$\frac{1}{\ln(2^N)}$$

Conversely, this implies that, on average, out of every $\ln(2^N) = N \cdot \ln(2) \approx 0.693 \cdot N$ randomly and independently selected integers from $(2^{N-1}, 2^N)$, one of them will be a prime number. For example, if $N = 1024$, then $0.693 \cdot N \approx 709.78$; in other words, if we are selecting random integers from $(2^{1023}, 2^{1024})$, then on average, we expect repeating approximately 710 times before we succeed in selecting a prime number. Note that $2^{1023} = 10^{1023 \times \log_{10}(2)} \approx 10^{1023 \times 0.301} \approx 10^{307.95}$.

- The Miller-Rabin Primality test
 - **Proposition** Let p be an odd prime and write $p - 1 = 2^k t$, where t is odd. Then, for each $a \in \mathbb{Z}$ with $p \nmid a$, one of the following is true:
 - $a^t \equiv 1 \pmod{p}$, or
 - One of $a^t, a^{2t}, a^{4t}, \dots, a^{2^{k-1}t}$ is congruent to $-1 \pmod{p}$.
 - **Corollary** Let $n \in \mathbb{Z}$ be an odd number, with $n - 1 = 2^k t$, t being odd. Then, n is composite, if any of the following is true:
 - There exists $a \in \mathbb{Z}$ such that $\gcd(a, n) > 1$.
 - There exists $a \in \mathbb{Z}$ such that $\gcd(a, n) = 1$, and $a^t \not\equiv 1 \pmod{n}$, and $a^{2^i t} \not\equiv -1 \pmod{n}$, for each $i = 0, 1, 2, \dots, k - 1$.
 - **Proposition** Let n be an odd composite number. Then, at least 75% of integers between 1 and $n - 1$ are Miller-Rabin witnesses for n .

1.4 Factorization algorithms

- Pollard's $p - 1$ factorization algorithm

This method “**probably**” works for producing a non-trivial factor for composite $n \in \mathbb{N}$ admitting a prime factor p such that $p - 1$ is a product of small primes.

- **Proposition:** Let $n = pq$, where p and q are distinct prime numbers. Then the following two statements hold:

- For each $L \in \mathbb{N}$, we have the following implications:

$$(p-1) \mid L \implies p \mid (a^L - 1)$$

- For any $a \in \mathbb{N}$ with $p \nmid a$ and $q \nmid a$, and any $L \in \mathbb{N}$,

$$\left. \begin{array}{l} p \mid (a^L - 1) \\ q \nmid (a^L - 1) \end{array} \right\} \implies p = \gcd(a^L - 1, n)$$

– **Key observations:**

- If $p-1$ is a product of small primes, then $p \mid N!$, for some not-too-large N .
- If $(q-1) \nmid N!$, then $q \nmid (a^{N!} - 1)$ is “probably” true.
- If $p-1$ is a product of small primes, and $q-1$ is NOT so, then computing $\gcd(a^{k!} - 1, n)$, for $k = 2, 3, \dots$, will “probably” yield p as a non-trivial factor of n .

- Factorization via difference of squares

– **Key observations:**

Suppose we know that $n \in \mathbb{N}$ is odd and composite. We want to find a non-trivial factor of n .

- If we can find $a, b \in \mathbb{N}$ such that n is the difference of their squares, i.e. $n = a^2 - b^2 = (a-b)(a+b)$, then computing $\gcd(a-b, n)$ will yield a non-trivial factor of n .
- Conversely, suppose $n = cd$. Since n is odd, both c and d must also be odd. Hence, $a := \frac{1}{2}(c+d) \in \mathbb{Z}$ and $b := \frac{1}{2}(c-d) \in \mathbb{Z}$. And, $a^2 - b^2 = \dots = cd = n$. In other words, every composite odd integer can be written as the difference of two squares.
- If some multiple kn is a difference of squares, i.e. $kn = a^2 - b^2 = (a-b)(a+b)$, then computing $\gcd(a-b, n)$ will “probably” yield a non-trivial factor of n , since it should be unlikely that n divides $a-b$.
- In summary, if we could find $a, b \in \mathbb{Z}$ such that $a^2 \equiv b^2 \pmod{n}$, then computing $\gcd(a-b, n)$ will probably yield a non-trivial factor of n .

– **Outline of general procedure:**

1. **Find B -smooth perfect squares in \mathbb{Z}_n .** Find many $a_1, a_2, \dots, a_r \in \mathbb{Z}$ such that every prime factor of $c_i \equiv a_i^2 \pmod{n}$ is less than or equal to B .
2. Find sub-collections $c_{i_1}, c_{i_2}, \dots, c_{i_s}$ such that $c_{i_1} c_{i_2} \dots c_{i_s} \equiv b^2 \pmod{n}$ are perfect squares in \mathbb{Z}_n .
3. Let $a := a_{i_1} a_{i_2} \dots a_{i_s} \pmod{n}$. Then, computing $\gcd(a-b, n)$ will probably yield a non-trivial factor of n .

– Comments on the general procedure:

- Step (3) can be performed efficiently using the Euclidean Algorithm.
- Step (2) is equivalent to solving a homogeneous (sparse) system of linear equations over \mathbb{F}_2 .
- The main challenge in difference-of-squares factorization is Step (1), namely, given $n \in \mathbb{Z}$, finding enough B -smooth perfect squares in \mathbb{Z}_n .

A Gibbs' Inequality & Jensen's Inequality

Theorem A.1 (Jensen's Inequality)

Suppose

- $(\Omega, \mathcal{A}, \mu)$ is a probability space (i.e. measure space with $\mu(\Omega) = 1$).
- $\varphi : (a, b) \rightarrow \mathbb{R}$ is a convex function, i.e.

$$\varphi(tx_1 + (1-t)x_2) \leq t\varphi(x_1) + (1-t)\varphi(x_2), \quad \text{for any } t \in [0, 1], \quad x_1, x_2 \in (a, b),$$

where $-\infty \leq a < b \leq \infty$.

- $g : \Omega \rightarrow (a, b)$ is a μ -integrable function.

Then, the following inequality holds:

$$\varphi\left(\int_{\Omega} g \, d\mu\right) \leq \int_{\Omega} \varphi \circ g \, d\mu$$

Corollary A.2 (Jensen's Inequality (Expectation Form))

Suppose

- $X : (\Omega, \mathcal{A}, \mu) \rightarrow (a, b)$ is a \mathbb{R} -valued random variable defined on the probability space $(\Omega, \mathcal{A}, \mu)$ with range contained in the open interval (a, b) , where $-\infty \leq a < b \leq \infty$.
- $\varphi : (a, b) \rightarrow \mathbb{R}$ is a convex function.

Then, the following inequality holds:

$$\varphi(E[X]) \leq E[\varphi(X)]$$

Theorem A.3 (Gibbs' Inequality)

Suppose

- (Ω, \mathcal{A}) is a measurable space.
- $f, g : \Omega \rightarrow [0, \infty)$ are two nowhere-vanishing probability density functions defined on (Ω, \mathcal{A}) .

Then, the following inequality holds:

$$-\int_{\Omega} (\log f) f \, dx \leq -\int_{\Omega} (\log g) f \, dx$$

PROOF First, note that $\varphi := -\log : (0, \infty) \rightarrow \mathbb{R}$ is a convex function defined on the open unit interval $(0, 1)$, and that the domain of φ contains the range of f and g . Hence, by Jensen's Inequality, we have:

$$\int_{\Omega} \left[-\log \left(\frac{g(x)}{f(x)} \right) \right] \cdot f(x) \, dx \geq -\log \left(\int_{\Omega} \frac{g(x)}{f(x)} \cdot f(x) \, dx \right) = -\log \left(\int_{\Omega} g(x) \, dx \right) = -\log(1) = 0$$

The above inequality immediately implies:

$$-\int_{\Omega} (\log g(x)) \cdot f(x) \, dx \geq -\int_{\Omega} (\log f(x)) \cdot f(x) \, dx,$$

which completes the proof of Gibbs' Inequality. □
